Notes: (1) Robust standard errors in parentheses. (2) Significant at *10%, **5%, and ***1% level. (3) Estimates show selection equation for the Garen (1984) methodology. We used generalized least squares (GLS) for estimation (Garen 1984). (4) Industry dummies, intercept, and control variables for firm age, prior profitability, culture of customer collaboration, culture of customer satisfaction, and low-tech industry are also included.
Note: This figure is not exhaustive and lists only some representative studies to show where our study fits in relation to relevant prior work.

Figure A1. Illustrative Literature
Appendix B

Additional Approaches for Addressing Endogeneity

This appendix reports additional results for addressing endogeneity. First, we estimated our models using an extension of the Garen (1984) model, which has been used in prior research for scenarios in which multiple potentially endogenous variables may be present (Luan and Sudhir 2010, pp. 446-448). Luan and Sudhir (2010) provide a method that corrects for endogeneity bias in continuous variables in cross-sectional data. This approach extends the Garen method to incorporate multiple endogenous variables. We provide a brief description of the methodology here. Suppose that we want to estimate the outcome equation of the following form to estimate effects of $A_j$ and $L_j$ on $S_j$:

\[ S_j = x_j'\beta + \gamma_jA + \gamma_jL + \epsilon_j \]

where the coefficients $\gamma_jA$ and $\gamma_jL$ are random coefficients composed of a systematic observed component and an unobserved component; $j$ is the unit of analysis (in our case, a firm):

\[ \gamma_j^A = w_j^A\theta^A + \phi_j^A \]

\[ \gamma_j^L = w_j^L\theta^L + \phi_j^L \]

where $w_j^A$ and $w_j^L$ are vectors that influence the marginal effects of $A_j$ and $L_j$ on $S_j$. Consider a set of exogenous variables collected in $z_j$ that influence the firm’s choice of endogenous variables $A_j$ and $L_j$:

\[ A_j = z_j'\lambda^A + \eta_j^A \]

\[ L_j = z_j'\lambda^L + \eta_j^L \]

Substituting (2) and (3) into (1), we get

\[ S_j = x_j'\beta + (w_j^A\theta^A)A + (w_j^L\theta^L) L + (\phi_j^A + \phi_j^L) + \epsilon_j \]

Luan and Sudhir show that this equation can be rewritten and estimated consistently as

\[ S_j = x_j'\beta + (w_j^A\theta^A)A + (w_j^L\theta^L) L + \eta_j^A + \eta_j^L \]

where $\eta_j^A$ and $\eta_j^L$ are, respectively, the estimated values of $\eta_j^A$ and $\eta_j^L$ from (4) and (5), and the $g$’s are the estimated coefficients of the endogeneity correction terms.

Thus, Luan and Sudhir’s approach consists of estimating equations (4) and (5), calculating the estimated $\eta_j^A$ and $\eta_j^L$, values, and substituting them into equation (7). In our situation, AIPC and RIPC are the endogenous variables $A_j$ and $L_j$, and Innovation is the outcome variable $S_j$. Table B1 shows the estimation of the selection equations (equations (4) and (5)). Table B2 shows the negative binomial and GLS estimations of the innovation equation (equation 7), controlling for the endogeneity-correction terms as suggested by Luan and Sudhir. The findings remain unchanged and similar to the results obtained using Garen’s methodology (Table 3).

Second, we adopt a two-step method first introduced by Heckman (1979) and used in other studies (e.g., Bharadwaj et al. 2007; Sampson 2007; Shaver 1998; Xu et al. 2014). We separate our sample firms into two groups: firms with scores above the mean on the sum of the standardized AIPC and RIPC variables, coded as 1, and firms below the mean on the sum, coded as 0. Intuitively, this binary variable (which we label HIGHRIAI) represents a high level of AIPC and RIPC in the firm. In this approach, endogeneity is addressed by calculating the Inverse Mills Ratio (IMR) using estimates from the first stage and including the IMR term in the second-stage equation as an additional predictor. The equations are

**Stage 1:** $P(\text{HIGHRIAI} = 1) = \Phi(\beta_0 + \beta_1W + u)$

**Stage 2:** Innovation = $f(\text{PCI, ICI, RIPC, AIPC, RIPC} \times \text{PCI, AIPC} \times \text{ICI, Inverse Mills Ratio, controls})$
where $W$ is the vector of variables in the first stage; $\Phi$ denotes the cumulative standard normal distribution function; and $u$ is the error term. We compute the IMR variable using estimates from the first stage. We calculate the IMR as $IMR = \Phi(\beta_r^*W)/\Phi(\beta_r^*W)$ if $HIGHRIAI = 1$ and $IMR = -\phi(\beta_r^*W)/(1 - \Phi(\beta_r^*W))$ if $HIGHRIAI = 0$, where $W$ and $\beta_r$ are, respectively, the vectors of independent variables and estimated coefficients from the first stage probit model, $\phi$ denotes the standard normal distribution function, and $\Phi$ denotes cumulative standard normal distribution function (Bharadwaj et al. 2007; Greene 2003; Shaver 1998). In the second stage, we include the IMR term as an additional control variable. This additional term appears in the equation because of potential endogeneity of AIPC and RIPC (as we discuss in the “Empirical Models and Econometric Considerations” subsection of the main text); namely, unobserved factors may influence AIPC and RIPC and so there is potential for endogeneity.2

The results using the Heckman approach (omitted for brevity) are qualitatively similar to the results using the Garen (1984) and Luan and Sudhir (2010) approaches. Like prior research that has used similar approaches and reached similar conclusions (e.g., Xu et al. 2014), the results confirm that although the correction terms may be significant, the estimates are robust, suggesting that endogeneity is not a significant concern in our study.
